Gene-Based Tests for Screening, Detection, and/or Management of Prostate Cancer

Effective: October 1, 2019

Next Review: September 2019
Last Review: September 2019

IMPORTANT REMINDER

Medical Policies are developed to provide guidance for members and providers regarding coverage in accordance with contract terms. Benefit determinations are based in all cases on the applicable contract language. To the extent there may be any conflict between the Medical Policy and contract language, the contract language takes precedence.

PLEASE NOTE: Contracts exclude from coverage, among other things, services or procedures that are considered investigational or cosmetic. Providers may bill members for services or procedures that are considered investigational or cosmetic. Providers are encouraged to inform members before rendering such services that the members are likely to be financially responsible for the cost of these services.

DESCRIPTION

There are a variety of gene-based biomarkers that have been associated with prostate cancer. These tests have the potential to improve the accuracy of risk prediction, diagnosis, staging, or prognosis of prostate cancer.

MEDICAL POLICY CRITERIA

Genetic tests for the screening, detection, and management of prostate cancer are considered investigational including but not limited to the following:

A. Single-nucleotide variants (SNVs) for risk assessment;
B. PCA3 for disease diagnosis;
C. TMPRSS fusion genes for diagnosis and prognosis;
D. Gene hypermethylation for diagnosis and prognosis;
E. Mitochondrial DNA variant testing for diagnosis;
F. Gene expression analysis, including but not limited to Prolaris®, Oncotype DX®, Prostate, and Decipher®.
NOTE: A summary of the supporting rationale for the policy criteria is at the end of the policy.

BACKGROUND

Prostate cancer is a complex, heterogeneous disease. At the extremes of the spectrum, if left untreated, some prostate cancers behave aggressively, metastasize quickly, and cause mortality, while others are indolent and never progress to cause harm. Current challenges in prostate cancer care are assessing risk; providing early and accurate detection; monitoring low-risk patients undergoing surveillance only; predicting recurrence after initial treatment; detecting recurrence after treatment; and assessing efficacy of treatment for advanced disease.

In response to the need for better biomarkers for risk assessment, diagnosis, and prognosis, a variety of exploratory research is ongoing. Some products of this work have already been translated or are in the process of being translated into commercially available tests, including:

- Single-nucleotide variants (SNVs) for risk assessment
- The Gen-Probe PROGENSA® PCA3 Assay (PCA3) for diagnosis
- TMPRSS fusion genes for diagnosis and prognosis
- Gene hypermethylation for diagnosis and prognosis
- Mitochondrial DNA variant testing for diagnosis
- Gene expression analysis for risk assessment and diagnosis, including Prolaris®, Oncotype DX® Prostate, and Decipher®

While studies using these tests generate information that may help elucidate the biologic mechanisms of prostate cancer and eventually help design treatments, the above-mentioned tests are currently in a developmental phase, without evidence of clinical utility for diagnosis, prognosis, or risk assessment. Many of the tests listed above have not been submitted to the U.S. Food and Drug Administration (FDA) for marketing clearance but, if available, are offered as laboratory-developed tests by Clinical Laboratory Improvement Amendments (CLIA) licensed laboratories.

SNV testing as part of genome-scanning tests with risk assessment for prostate cancer is offered by a variety of laboratories including Navigenics, LabCorp (23andme), and ARUP (deCode) as laboratory-developed tests. The PCA3 test is offered in the U.S. by reference laboratories including ARUP, Mayo Medical Laboratories, and LabCorp. The reagents used in testing are developed by Gen-Probe. A test for hypermethylation of GSTP1 was available from LabCorp (“Glutathione S-transferase Gene [GSTP1, pi-class] Methylation Assay”); but as of January 2015, this test is no longer offered.

ConfirmMDx is offered from MDxHealth. The tissue-based DNA methylation multigene assay aims to improve stratification of men being considered for repeat prostate biopsy. Hypermethylation of GSTP1, APC, and RASSF1 are assessed in core biopsy samples.
SelectMDx for Prostate Cancer is also offered from MDxHealth. The reverse transcription PCR (RT-PCR) assay is performed on post-DRE (digital rectal examination), first-void urine specimens from patients with clinical risk factors for prostate cancer, who are being considered for biopsy. The test measures the mRNA levels of the *DLX1* and *HOXC6* biomarkers, using *KLK3* expression as internal reference, to aid in patient selection for prostate biopsy.

**REGULATORY STATUS**

One mitochondrial DNA test, Mitomics (Broomfield, CO), is currently available. Mitomics offers the Prostate Core Mitomics Test which measures mitochondrial DNA variants in a negative prostate biopsy to determine whether a patient should undergo repeat biopsy. The test is performed on the initial negative prostate biopsy tissue.

The PROGENSA® PCA3 Assay was approved by the FDA on February 15, 2012 through the premarket approval process. According to the approval granted by the FDA:[1]

“The PROGENSA PCA3 Assay is indicated for use in conjunction with other patient information to aid in the decision for repeat biopsy in men 50 years of age or older who have had one or more previous negative prostate biopsies and for whom a repeat biopsy would be recommended by a urologist based on current standard of care, before consideration of PROGENSA PCA3 assay results.”

Prolaris®, Oncotype DX® Prostate, and Decipher® gene expression profiling test are available under the auspices of CLIA. Laboratories that offer LDTs must be licensed by CLIA for high-complexity testing. To date, the U.S. Food and Drug Administration (FDA) has chosen not to require any regulatory review of this test.

In November 2015, the FDA’s Office of Public Health Strategy and Analysis published a document on public health evidence for FDA oversight of LDTs.[2] FDA argued that many tests need more FDA oversight than the regulatory requirements of CLIA. CLIA standards relate to laboratory operations, but do not address inaccuracies or unreliability of specific tests. Prolaris® is among the 20 case studies in the document cited as needing FDA oversight. The document asserted that patients are potentially receiving inappropriate prostate cancer care because there is no evidence that results from the test meaningfully improve clinical outcomes.

The other tests mentioned in this policy, if available, are offered as laboratory-developed tests under the Clinical Laboratory Improvement Amendments (CLIA) licensed laboratories.

**EVIDENCE SUMMARY**

Human Genome Variation Society (HGVS) nomenclature[3] is used to describe variants found in DNA and serves as an international standard. It is being implemented for genetic testing medical evidence review updates starting in 2017. According to this nomenclature, the term “variant” is used to describe a change in a DNA or protein sequence, replacing previously-used terms, such as “mutation.” Pathogenic variants are variants associated with disease, while benign variants are not. The majority of genetic changes have unknown effects on human health, and these are referred to as variants of uncertain significance.

In general, the evidence for genetic tests related to prostate cancer screening, detection, and management addresses either preliminary clinical associations between genetic tests and disease states or, in some cases, the clinical validity of these tests i.e., the association of the test result with outcomes of interest, expressed in terms of clinical performance characteristics.
such as sensitivity, specificity, predictive value, and comparisons to current standards using receiver-operating curve (ROC) analysis and/or logistic regression. There is no published evidence demonstrating clinical utility (i.e., a test will change treatment decisions and improve patient important outcomes).

GEbazh-Based Teszal IN GENERAL

A 2009 BlueCross BlueShield Association (BCBSA) TEC Special report of recently published studies on gene-based tests (SNVs, PCA3, TMPRSS, gene panels, and gene hypermethylation) for prostate cancer risk assessment and diagnosis concluded that, in general, research on these tests is still in a “developmental phase, currently without evidence of clinical utility.”[4] This policy was initially based on a 2013 BlueCross BlueShield Association Technology Evaluation Center (TEC) Assessment which was updated in January 2015 with a literature review through September 30, 2014.[5,6] Full-length publications were sought that described the analytic validity (technical performance), clinical validity (prognostic accuracy), and clinical utility (accurately identifying men experiencing improved health outcomes by avoiding treatment or undergoing more appropriate therapies) of Prolaris, Oncotype DX Prostate, and Decipher® gene expression profiling. The Blue Cross Blue Shield Association Medical Advisory Panel also reviewed the evidence in September 2017.

SINGLE-NUCLEOTIDE VARIANTS (SNVS) FOR PROSTATE CANCER RISK ASSESSMENT AND PROGNOSIS

There have been numerous large observational correlational studies focusing on the association of many different SNVs with prostate cancer, an example of which includes the study by Lindstrom of 10,501 cases of prostate cancer and 10,831 controls, which identified 36 SNVs showing association with prostate cancer risk including two (rs2735893 and rs266849) showing differential association with Gleason grade. Per allele odds ratios ranged from 1.07 to 1.44.[7]

Because the SNVs individually provide relatively modest incremental information on both the occurrence of cancer and its behavior, investigators have begun to explore use of algorithms incorporating information from multiple SNVs to increase the clinical value of testing. Several such recent studies focused on the development of testing algorithms incorporating SNVs.[8-11]

Systematic Reviews

A systematic review of multigene panels for prostate cancer risk assessment was published by Little (2016).[12] The authors included 21 studies that evaluated 18 individual panels. All studies were focused on clinical validity, moderate risk of bias, and had poor discriminative ability for predicting prostate cancer risk and/or distinguishing between aggressive and latent cancers. The authors noted that the current evidence is insufficient to assess analytic validity, and that “at best the panels assessed would add a small and clinically unimportant improvement” to current factors used for risk stratification, like age and family history. Additionally, they found no evidence on the clinical utility of these panels.

A 2012 AHRQ report on multigene panels in prostate cancer risk assessment, also by Little, reviewed the literature on SNV panel tests for assessing risk of prostate cancer.[13] All of the studies included in the review had poor discriminative ability for predicting risk of prostate cancer, had moderate risk of bias, and none of the panels had been evaluated in routine clinical settings. The conclusions of the review were that the evidence on currently available
SNV panels does not permit meaningful assessment of analytic validity, the limited evidence on clinical validity is insufficient to conclude that SNV panels would perform adequately as a screening test and that there is no evidence available on the clinical utility of current panels.

Ishaak (2011) reviewed 11 replication studies involving 30 SNVs (19 in men of African descent and 10 in men with familial prostate cancer). Odds ratios were positively associated with prostate cancer, although the magnitude of association was generally small (range 1.11 to 2.63).

Amin Al Olama (2013) conducted a meta-analysis of four GWASs including 5,953 cases of aggressive prostate cancer (PCa) and 11,463 controls. Authors computed association tests for approximately 2.6 million SNVs and followed up the most significant SNVs by genotyping 49,121 samples in 29 studies through the international PRACTICAL and BPC3 consortia. The authors confirmed the association of a PCa susceptibility locus, rs11672691 on chromosome 19, but also showed an association with aggressive PCa (odds ratio [OR] 1.12, 95% confidence interval [CI] 1.03 to 1.21, p=1.4 ×10^-8). The authors concluded their report described a genetic variant which is associated with aggressive PCa, and which is a type of PCa associated with a poorer prognosis.

Nonrandomized Studies

A pilot study by Castro (2016) tested the use of a 71-SNV panel in 100 men with a family history of prostate cancer. These men underwent a prostate biopsy regardless of PSA level, and 25 were diagnosed with prostate cancer. Age and PSA level were significantly associated with a cancer diagnosis, but the SNV risk score was not. While this study might not have been adequately powered to detect such an association, there was a clear relationship seen for age and PSA level (p=0.00004 and 0.00037, respectively).

Kader (2012) evaluated a panel of 33 SNVs associated with prostate cancer in 1,654 men. Genetic score was a significant (p<0.001) independent predictor of prostate cancer (OR 1.72, 95% CI 1.44 to 2.09) after adjustment for clinical variables and family history. Addition of genetic markers to the classification of prostate cancer risk resulted in 33% of men reclassified into a different risk quartile. Approximately half of these (n=267) were downgraded to a lower risk quartile and the other half (n=265) were upgraded into a higher risk quartile. The net reclassification benefit was 10% (p=0.002). The authors concluded that with the additional information of genetic score the same number of cancers could be detected by using 15% fewer biopsies. However, this study includes a limited sample size and there is no clear indication of how clinical management changed when patients were reclassified into lower risk groups.

Ren (2013) calculated genetic scores for various combinations of 29 PCa risk-associated SNVs in 667 consecutive patients that underwent prostate biopsy. Performance of these genetic scores for discriminating prostate biopsy outcomes were compared using the area under a receiver operating characteristic curve (AUC). The discriminative performance of genetic score derived from a panel of all 29 SNVs (24 previous and five new) was similar to that derived from the 24 previously established SNVs, the AUCs of which were 0.60 and 0.61, respectively (p=0.72). Authors concluded that genetic score based on PCa risk-associated SNVs implicated to date is a significant predictor of biopsy outcome.

Tsuchiya (2013) identified 14 SNVs in six genes (XRCC4, PMS1, GATA3, IL13, CASP8, and IGF1) that were statistically associated with cancer-specific survival. Using a subset of six
SNVs, three subgroups of men with prostate cancer were defined by the number of SNV’s present (0 to 1, 2 to 3, or 4 to 6). Median cancer-specific survival in these subgroups was 13.3, 7.0, and 3.8 years, respectively (log-rank test, p<0.001).

Section Summary

Numerous studies have demonstrated the association of many gene panels and SNVs with prostate cancer. These studies, in early stages of development, have shown a modest degree of association with future risk for prostate cancer. The clinical utility of these tests is uncertain; there is no evidence that information obtained from gene panels or SNV testing can be used to change clinical management in ways that will improve outcomes.

**PCA3 FOR PROSTATE CANCER DIAGNOSIS**

*PCA3* is overexpressed in prostate cancer and *PCA3* mRNA can be detected in urine samples collected after prostate massage. When normalized using PSA to account for the amount of prostate cells released into the urine (*PCA3* Score), the test has been proposed for use in discriminating between patients with eventual benign findings on (first or second) biopsies from those with malignant biopsy results. In particular, the test may be especially helpful at identifying patients with elevated PSA levels but negative first biopsy results who need a follow-up biopsy.

Systematic Reviews

Cui (2016) reported on results of a systematic review that searched PubMed and EMBASE for case-control or cohort studies of the PROGENSA® PCA3 test.[20] Quality was assessed using the QUADAS tool. Pooled estimates were calculated using random-effects models and categorized ROCs when evidence of threshold effect was detected. The review included 46 studies with over 12,000 men. The quality of the selected studies was rated as moderate to high. The most common *PCA3* cutoff for categorizing low and high risk was 35; 25 studies had a *PCA3* cutoff of 35. Most were performed in the United States and Europe; five were conducted in Asia. The estimates of AUC were lower for studies including men having repeated (0.68, 95% CI 0.67 to 0.70) vs initial (0.80, 95% CI 0.78 to 0.82) biopsies. AUC values were 0.74 (95% CI 0.73 to 0.76) for studies with a cutoff value of 35 and 0.77 (95% CI 0.75 to 0.79) for studies with a cutoff value not equal to 35, although the group with varying cutoff (≠35) had a greater range and more variable performance estimates.

Nicholson (2015) published a health technology assessment on behalf of the National Health Service in England and Wales.[21] Publications from 2000 to May 2014 were included in a systematic review. Participants were men suspected of having prostate cancer for whom the results of an initial prostate biopsy were negative or equivocal; and a *PCA3* score or phi in combination with existing standard tests, multiparametric MRI and clinical judgement were evaluated for analytic validity and clinical validity. Overall, six studies met inclusion for the analytical validity review; and fifteen studies met inclusion for the clinical validity review. The authors found issues regarding the precision of the *PCA3* assay measurements, and insufficient evidence to identify useful clinical thresholds.

In 2013, the Agency for Healthcare Quality and Research (AHRQ) published a comparative effectiveness review entitled, “*PCA3* Testing for the Diagnosis and Management of Prostate Cancer.”[22] Literature was searched and updated through May 15, 2012. Forty-three studies were included; all were rated poor quality. In their conclusion, the authors stated, “For
diagnostic accuracy, there was a low strength of evidence that PCA3 had better diagnostic accuracy for positive biopsy results than [serum] total PSA elevations, but insufficient evidence that this led to improved intermediate or long-term health outcomes. This finding appeared to apply to both initial and repeat biopsies. Evidence was insufficient to assess the use of PCA3 in treatment decision-making for men with positive biopsy.

In a 2012 systematic review, authors discuss the potential use of genetic markers to better define groups of men at high risk of developing prostate cancer, to improve screening techniques, discriminate indolent versus aggressive disease, and improve therapeutic strategies in patients with advanced disease. Genetic tests for PCA3 and TMPRSS2-ERG genes were included. Authors concluded that most markers have not been prospectively validated for providing useful prognostic or predictive information or improvement upon clinicopathologic parameters already in use.

A meta-analysis by Ruiz-Aragon (2010) reviewed 14 studies of PCA3 for use in predicting prostate biopsy results. Sensitivity of testing ranged from 47% to 82% and specificity from 56% to 89%. Global results provided a sensitivity of 85% (CI 84 to 87) and a specificity of 96% (CI 96 to 97). No publications on how this information affected decision making or either short- or long-term outcomes has been published.

**Randomized Controlled Trials**

In 2014, the National Cancer Institute conducted a prospective trial to validate the diagnostic use of PCA3 to complement PSA-based detection of prostate cancer. The target population included men who had been screened for prostate cancer, primarily with a PSA test, some of whom had undergone a previous prostate biopsy. The study included 859 men from 11 centers in the United States. The primary study endpoint was the diagnosis of prostate cancer on biopsy and the secondary study endpoint was diagnosis of high grade prostate cancer, defined as a Gleason score greater than 6. The primary analyses, including PCA3 thresholds, were determined a priori, and statistical power was based on independent analyses of prevalidation data from similar cohorts. Of the men in the study, 562 were presenting for their initial prostate biopsy. Positive predictive value was 80% (95% CI 72% to 86%), and using a PCA3 score of more than 60, diagnostic sensitivity and specificity of PCA3 was 0.42 (95% CI 0.36 to 0.48) and 0.91 (95% CI 0.87 to 0.94), respectively. For patients who underwent a repeat biopsy, the NPV was 88% (95% CI, 81% to 93%), and by using a PCA3 score of less than 20, sensitivity and specificity were 0.76 (95% CI 0.64 to 0.86) and 0.52 (95% CI 0.45 to 0.58), respectively. For the detection of high grade cancer, PCA3 performance in combination with Prostate Cancer Prevention Trial’s (PCPT) risk calculator was improved by the addition of PCA3 to the PCPT risk calculator factors with an AUC improvement of 0.74 to 0.78 for initial biopsy and 0.74 to 0.79 on repeat biopsy (p≤0.003).

**Nonrandomized Studies**

Several studies published between 2013 and 2018 reported positive associations between PCA3 levels and prostate cancer diagnosis. Predictive value was increased when PCA3 testing was combined with PSA level and other clinical information. Other groups reported moderate diagnostic accuracy of PCA3 testing. Among men with PSA level greater than 3 ng/mL, AUC of PCA3 was 0.74. Conversely, in men with PCA3 scores of 100 or greater, positive predictive value was 39%. In a multicenter study of 647 men, sensitivity and specificity were 67% and 72%, respectively; AUC was 0.742. Three studies compared PCA3 to multiparametric MRI; MRI was more accurate than PCA3, but the combination was
better than either alone.[43] PCA3 has also been associated with the risk of Gleason grade reclassification in a study of 90 men receiving 5α-reductase inhibitor therapy during active surveillance.[44]

Clinical utility studies using assay results for decision-making for initial biopsy, repeat biopsy, or treatment have not been reported. One group reported potential reductions in unnecessary biopsies of 48 to 52% with attendant increases in missed prostate cancers of 6 to 15% using either a PCA3-based nomogram[45] or PCA3 level corrected for prostate volume (PCA3 density).[46] Although both studies were prospective, neither assessed utility of the test for clinical decision-making because all patients underwent biopsy, and recurrence or survival outcomes were not evaluated. Another group evaluated the estimated long-term impact of using the PCA3 score to guide the decision to recommend a repeat biopsy for men with elevated PSA levels.[47] Their models suggested that using a PCA3 score threshold of 25 would result in 55.4% reduction in repeat biopsies for a base-case patient, while reducing the 10-year survival by 0.93%. However, these estimates have not been validated in real patient populations.

Section Summary

Studies of PCA3 as a diagnostic test for prostate cancer reported sensitivities and specificities in the moderate range. In general, these studies are preliminary and report on clinical performance characteristics in different populations and with various assay cutoff values, reflecting the lack of standardization in performance and interpretation of PCA3 results. Several studies have reported a modest incremental improvement in diagnostic accuracy when PCA3 was tested in combination with PSA level and other clinical findings. The clinical utility of this test is uncertain, as there is insufficient evidence that the use of PCA3 can be used to change management in ways that improve outcomes.

TMPRSS FUSION GENES

TMPRSS2 fusion gene detection has been studied for prognostic value (e.g., to identify aggressive disease or to predict disease recurrence). In prostate cancer, it may be fused to an ETS family transcription factor (ERG, ETV1, ETV4, or ETV5), which modulates transcription of target genes involved in cell growth, transformation, and apoptosis (TMPRSS2:ERG). The result of gene fusion with an ETS transcription gene is that the androgen-responsive promoter of TMPRSS2 upregulates expression of the ETS gene, suggesting a mechanism for neoplastic transformation. Fusion genes may be detected in tissue, serum, or urine.

Systematic Review

Yao (2014) published a systematic review with meta-analysis of TMPRSS2:ERG for the detection of prostate cancer.[48] Literature was searched and 32 articles were identified. Pooled sensitivity, specificity, positive likelihood ratio, and negative likelihood ratio were 47% (95% CI 46 to 49), 93% (95% CI 92 to 94), 8.9 (95% CI 5.7 to 14.1), and 0.49 (95% CI 0.43 to 0.55), respectively. Statistical heterogeneity was high (I²>85%). It was unclear whether studies in screening populations were pooled with enriched patient samples, e.g., elevated PSA and/or biopsy-negative. There also was variability in the type of tissue samples analyzed (urine, prostatic secretions, biopsy or surgical specimens); the type of TMPRSS2:ERG assays used (fluorescence in situ hybridization [FISH], immunohistochemistry [IHC], real-time reverse transcriptase polymerase chain reaction [RT-PCR], and transcription-mediated amplification); and in TMPRSS2:ERG threshold cutoff values.
Nonrandomized Studies

Leyton (2014) investigated the predictive value of PCA3 and TMPRSS2 as individual biomarkers and as part of a panel in a prospective, multicenter study of 443 men.[49] TMPRSS2 was found to be highly specific (93%) for predicting clinically significant prostate cancer on biopsy. Because of this high specificity, the authors suggested that re-biopsy or magnetic resonance imaging (MRI) be performed in TMPRSS2:ERG-positive patients who do not have prostate cancer detected on initial biopsy. The authors stated that if PCA3 in combination with TMPRSS2 data had been used to select men for prostate biopsy, 35% of biopsies could have been avoided. However, the clinical utility of this test is uncertain, as there are no studies that report the test leads to changes in management that result in improved health outcomes.

Whelan (2014) compared two multivariate models to assess up-staging in 216 patients meeting National Comprehensive Cancer Network (NCCN) criteria for active surveillance.[50] One model included TMPRSS2:ERG plus serum PSA; the other model included serum PSA, total RNA in expressed prostatic secretion (EPS, collected by milking the urethra after prostatic massage), and total EPS volume. AUCs were similar (0.80, 95% CI 0.75 to 0.85] and 0.79, 95% CI 0.73 to 0.84], respectively). However, the second model was more accurate for detecting patients who were up-staged, or up-staged and up-graded, by NCCN criteria. Specifically, the second model decreased the risk of up-staging in patients with a negative test approximately eight-fold (from 7% to 1%); decreased the risk of up-staging plus up-grading approximately five-fold (from 5% to 1%); and doubled the prevalence of up-staging in the positive test group. In comparison, the TMPRSS2:ERG model decreased up-staging 2.4-fold (from 7% to 3%) and decreased upstaging and upgrading approximately three-fold (from 5% to 2%).

A modeling study by Merdan (2015) estimated that using a TMPRSS2:ERG score to guide repeat biopsy decisions in men with elevated PSA could avoid 64.7% of these biopsies, but also reduce the 10-year survival rate by 1.4%.[47] These estimations have not been validated in real-world trials.

A number of studies have reported positive associations between TMPRSS2 fusion gene levels and prostate cancer diagnosis.[30,31,51,52] One study reported a lack of association between TMPRSS2:ERG status and biochemical relapse-free rate in 244 men treated with image-guided radiotherapy (IGRT) for prostate cancer.[53] The authors concluded that “TMPRSS2:ERG is therefore unlikely to be a predictive factor for IGRT response.”

No studies of clinical utility have been published to date; the evidence consists of correlational studies (association between a fusion gene and prostate cancer).[54-57] However, the results of available studies differ as to the accuracy of TMPRSS2:ERG in improving the ability to predict prostate cancer, and/or the ability to estimate prognosis for this purpose.

Section Summary

Limited evidence reports that the measurement of TMPRSS2:ERG may improve the ability to predict prostate cancer, and/or the ability to estimate prognosis. However, the results of available studies differ as to the accuracy of TMPRSS2:ERG for this purpose. In addition, the clinical utility of this test is uncertain.

TMPRSS2:ERG IN COMBINATION WITH PCA3

Nonrandomized Studies
Tomlins (2011) developed a transcription-mediated amplification assay to measure \( \text{TMPRSS2:ERG} \) fusion transcripts in parallel with \( \text{PCA3} \).\(^{[57]} \) Combining results from these two tests and incorporating them into the multivariate Prostate Cancer Prevention Trial risk calculator improved the identification of patients with clinically significant cancer by Epstein criteria and high-grade cancer on biopsy. Though the study was large (1,312 men at multiple centers), results were confounded by assay modifications during the course of the study, by the use of cross-validation rather than independent validation, and the use of independent training and testing sets. A validation study by the same group evaluated this risk prediction model (termed Mi-Prostate Score or MiPS), which incorporated serum PSA with urine \( \text{TMPRSS2:ERG} \), and \( \text{PCA3} \), in a group of 1244 men presenting for biopsy.\(^{[58]} \) They reported that it improved on PSA alone for predicting prostate cancer and high-grade prostate cancer, but did not assess the clinical utility of this risk score.

A study by Feibus (2016) evaluated the clinical use of \( \text{PCA3} \) and \( \text{TMPRSS2:ERG} \) in African-American men undergoing prostate biopsy.\(^{[33]} \) This study included 182 African-American and 139 non-African-American patients. They found that \( \text{PCA3} \) and \( \text{TMPRSS2:ERG} \) scores were associated with prostate cancer, and adding \( \text{PCA3} \) to a standard of care plus PSA model improved concordance statistics for the detection of any prostate cancer in both groups. However, \( \text{PCA3} \) score was only predictive of high grade prostate cancer in African-Americans and not in non-African-Americans, while \( \text{TMPRSS2:ERG} \) did not improve these measures in either group.

In a pilot study, Salami (2013) evaluated 45 men using a multivariable algorithm that included serum PSA plus urine \( \text{TMPSS2:ERG} \) and \( \text{PCA3} \) from a post-DRE sample.\(^{[59]} \) Samples were collected before prostate biopsy at two centers. For cancer prediction, sensitivity and specificity were 80% and 90%, respectively. AUC was 0.88. Limitations in this study included the small number of patients and authors used a quantitative RT-PCR assay to measure \( \text{PCA3} \) in urine sediment, and evaluation of this model with the commercially available TMA assay of whole urine would help inform broader clinical applicability. Authors concluded a larger validation study could determine whether a multiplex model combining \( \text{PCA3}, \text{TMPRSS2:ERG} \) and serum PSA can predict aggressive versus indolent prostate cancer than any of these biomarkers alone.

Robert (2013) retrospectively examined tissue levels of \( \text{TMPRSS2:ERG} \) and \( \text{PCA3} \) in 48 men with benign prostatic hypertrophy, 32 men with normal prostate tissue sampled next to prostate cancer, and 48 men with prostate cancer.\(^{[60]} \) Sensitivity, specificity, and positive and negative predictive values for the tests in combination were 94%, 98%, 96%, and 96%, respectively. The limitations of the study included that not all samples were confirmed with a diagnosis, there was a lack of urinary data, and the study results are not generalizable to clinical practice.

**Section Summary**

Concomitant detection of \( \text{TMPRSS2:ERG} \) and \( \text{PCA3} \) may accurately identify men with prostate cancer. However, estimated accuracy varies across the available studies and clinical utility has not been established.

**GENE HYPERMETHYLATION FOR PROSTATE CANCER DIAGNOSIS AND PROGNOSIS**

**Nonrandomized Studies**
Several studies have reported associations between DNA hypermethylation at various gene loci (RASSF1A, APC, GSTP1, PTGS2, RAR-beta, TIG1, AOX1, C1orf114, GAS6, HAPLN3, KLF8, and MOB3B) and prostate cancer. In contrast, some studies have not found evidence of an association. Further, Kachakova (2013) concluded that HIST1H4K hypermethylation was more likely due to aging than to prostate carcinogenesis. ConfirmMDx (MDxHealth) is a commercially available test for gene methylation intended to distinguish true-from false-negative prostate biopsies to avoid the need for repeat biopsy in cases of a true negative and to identify men who may need a repeat biopsy. The test measures methylation of the genes GSTP1, APC, and RASSF1.

Two blinded multicenter validation studies of the ConfirmMDx test have been performed. Partin (2014) reported on results of the DOCUMENT study; it evaluated archived, cancer-negative prostate biopsy core tissue samples from 350 men from five U.S. urology centers. All patients underwent repeat biopsy within 24 months. Men with two consecutive negative biopsies were classified as controls and men with a negative biopsy followed by a positive biopsy were classified as cases. Thirty (9%) men were excluded from analysis because of noneligibility (n=2), insufficient DNA (n=1), insufficient biopsy cores (n=23), or detection of adenocarcinoma in the first biopsy based on central pathology review (n=4); 320 men were included in analysis (92 cases, 228 controls). Median age was 62 years (range, not given). Median PSA level was 5.3 ng/mL; 23% of men had PSA levels less than 4 ng/mL and 10% had a PSA level of 10 ng/mL or higher. Sixty percent of men had a normal DRE. Forty-two (13%) of the men were black, 232 (73%) were white, and 13 (4%) were Asian. The ConfirmMDx test, performed on the first biopsy, resulted in a NPV of 88% (95% CI 85% to 91%), sensitivity of 62% (95% CI 51% to 72%), and specificity of 64% (95% CI 57% to 70%). The study was not powered to determine accurately the performance characteristics in a subgroup of black patients, but the estimated sensitivity was 77% (95% CI 46% to 95%), specificity was 66% (95% CI, 46% to 82%), and NPV was 93% (85% CI 82% to 97%). Multivariate analysis of potential predictors of cancer on repeat biopsy, corrected for age, PSA, DRE, first biopsy histopathology characteristics, and race, showed that the ConfirmMDx test was the most significant independent predictor of patient outcome (OR 2.69, 95% CI 1.60 to 4.51).

The MATLOC study, reported by Stewart (2013), tested archived cancer-negative prostate biopsy needle core tissue samples from 498 men from the U.K. and Belgium. Patients underwent repeat biopsy within 30 months; cases had a positive second biopsy while controls had a negative second biopsy. A total of 483 men were included in the analysis (87 cases, 396 controls). The median PSA level was 5.9 ng/mL; 21% of men had PSA levels less than 4 ng/mL and 18% had PSA levels of 10 ng/mL or higher. Seventy-three percent of men had benign DRE. The ConfirmMDx test, performed on the first biopsy, resulted in a NPV of 90% (95% CI 87% to 93%), sensitivity of 68% (95% CI 57% to 77%), and specificity of 64% (95% CI 59% to 69%). Multivariate analysis of potential predictors of cancer on repeat biopsy, corrected for patient age, PSA, DRE, and first biopsy histopathology characteristics, showed that the ConfirmMDx test was the most significant independent predictor of patient outcome (OR 3.17, 95% CI 1.81 to 5.53).

Van Neste (2016) reported on results of combined data from the DOCUMENT and MATLOC studies to investigate whether DNA methylation intensities were associated with high-grade (Gleason score, ≥7) prostate cancer. DNA methylation was the most significant and important predictor of high-grade cancer, resulting in an NPV of 96% (precision not reported).
Wojno (2014) reported on a field observation study in which practicing urologists at 5 centers used the ConfirmMDx test to evaluate at least 40 men with previous cancer-negative biopsies who were considered at risk for prostate cancer.[78] Centers reported whether patients who had a negative test assay result had undergone a repeat biopsy at the time of the analysis. Median patient follow-up after the assay results were received was nine months. A total of 138 patients were included in the analysis. The median PSA level was 4.7 ng/mL. Repeat biopsies had been performed in six (4.3%) of the 138 men with a negative ConfirmMDx test, in which no cancer was identified.

Aubry (2013) analyzed the expected reduction in biopsies associated with ConfirmMDx use.[79] Using the MATLOC estimates of performance characteristics for ConfirmMDx, the authors estimated that 1,106 biopsies per one million people would be avoided. The study did not include decision analysis comparing the tradeoff in reduction in biopsies and missed cancers.

Section Summary

Studies evaluating the diagnostic accuracy and predictive ability of gene hypermethylation report differing results regarding the accuracy of hypermethylation. These inconsistent results make it difficult to determine whether hypermethylation is a useful parameter for diagnosis and/or prognosis of prostate cancer. Two clinical validation studies have reported on the clinical validity of the ConfirmMDx score in the intended use population. The studies did not provide estimates of validity compared with a standard clinical examination with percent free PSA. No data are available on the long-term clinical outcomes or clinical utility of the test. The indirect chain of evidence is incomplete due to the limitations of evidence on the comparative clinical validity and utility.

MITOCHONDRIAL DNA VARIANT TESTING

Variants in the mitochondrial genome (mtDNA) are emerging as tools for the diagnosis of prostate cancer. A growing body of literature is reporting significant associations between both single nucleotide changes and large-scale deletions in mtDNA and prostate cancer, however, the identified studies are of small to medium sample size and do not address clinical utility. A laboratory developed assay offered by Mitomics (formerly Genesis Genomics), called the Prostate Core Mitomics Test™ (PCMT), is a proprietary test which is intended to determine whether a patient has prostate cancer, despite a negative prostate biopsy, by analyzing deletions in mitochondrial DNA by PCR to detect “tumor field effect”. The test is performed on the initial negative prostate biopsy tissue. According to the company website, a negative PCMT result confirms the results of the negative biopsy (i.e., the patient doesn’t have prostate cancer) and that the patient can avoid a second biopsy, but that a positive PCMT means that the patient is at high risk of undiagnosed prostate cancer. The company website states that the sensitivity of the test is 85% and has a negative predictive value of 92%.

Nonrandomized Studies

A trial published in 2016 examined the role of the mitochondrial genome in prostate cancer risk in 4,086 prostate cancer cases and 3,698 controls from the Multiethnic Cohort.[80] In this study, 350 mitochondrial SNVs were tested in five racial/ethnic populations: Asian Americans, Africans, Europeans, Latinos, and Native Hawaiians. No significant associations were found.

Published literature from Genesis Genomics on the use of mitochondrial DNA variants in prostate includes several studies. A 2006 study retrospectively analyzed mitochondrial DNA
variants from three tissue types from 24 prostatectomy specimens: prostate cancer, adjacent benign tissue and benign tissue distant to the tumor (defined as tissue from a nondiseased lobe or at least 10 cell diameters from the tumor if in the same lobe). Prostate needle biopsy tissue from 12 individuals referred for biopsy that were histologically benign were used as controls. Results from the prostatectomy tissue analysis showed that 16 of 24 (66.7%) had variants in all three tissue types, 22 of 24 (91.7%) had variants in malignant samples, 19 of 24 (79.2%) in adjacent benign samples and 22 of 24 in distant benign glands. Overall, 273 somatic variants were observed in this sample set. In the control group, seven (58.3%) patients were found to have between one and five alterations, mainly in non-coding regions. The authors concluded that the variants found in the malignant group versus the control group were significantly different and that mitochondrial DNA variants are an indicator of malignant transformation in prostate tissue.

Maki (2008) reported the discovery and characterization of a 3.4-kb mitochondrial genome deletion and its association with prostate cancer. A pilot study analyzed 38 benign biopsy specimens from 22 patients, 41 malignant biopsy specimens from 24 patients and 29 proximal to malignant (PTM) biopsy specimens from 22 patients. All of the patients with malignant biopsies had a subsequent prostatectomy, and the diagnosis of cancer was confirmed. The PTM biopsy samples were negative for cancer and were from the cohort who underwent prostatectomy. A confirmation study used 98 benign biopsy specimens from 22 patients, 75 malignant biopsy specimens from 65 patients, and 123 PTM biopsy specimens from 96 patients. In the confirmation study, patients were required to have at least two successive negative biopsies; the first negative biopsy was used for analyses. For both the pilot and confirmation studies, samples for analysis were selected based upon review of pathology reports. The levels of the variant were measured by quantitative PCR and using PCR cycle threshold data were used to calculate a score for each biopsy sample. In the pilot study, the scores were statistically significant between benign and malignant (p<0.0001) and benign and proximal (p<0.003) samples. The PTM samples closely resembled the malignant sample, with no statistical significant resolution between their scores (p<0.833), to which the authors attributed as a field cancerization phenomenon. Results from the larger confirmation study were similar. Compared with histopathologic examination of the benign and malignant samples, the sensitivity and specificity were 80% and 71%, respectively, and the area under a ROC curve was 0.83 for the deletion. A blinded, external validation study showed a sensitivity and specificity of 83% and 79% and an AUC of 0.87.

Robinson (2010) assessed the clinical value of the 3.4-kb deletion described in the Maki (2008) study in predicting re-biopsy outcomes. Levels of the deletion were measured by quantitative PCR in prostate biopsies negative for cancer from 101 patients who underwent repeat biopsy within a year and had known outcomes. Of the 101 first biopsies, the diagnosis was normal in eight, atypical and/or had prostatic intraepithelial neoplasia (PIN) in 50 and hyperplasia or inflammation in 43. Using an empirically established cycle threshold cutoff, the lowest cycle threshold as diagnostic of prostate cancer, and the histopathologic diagnosis on second biopsy, the clinical performance of the deletion was calculated. The final data was based on 94 patients, who on second biopsy had 20 malignant and 74 benign diagnoses. The cycle cutoff gave a sensitivity and specificity of 84% and 54%, respectively, with AUC of 0.75. Negative predictive value was 91%.

Section Summary
Studies using the PCMT test for the diagnosis of prostate cancer reported sensitivities and specificities in the moderate range. In general, these studies are preliminary and only report on clinical validity. There is a lack of standardization in methodology and the clinical utility of this test was not addressed.

**GENE EXPRESSION ANALYSIS**

**Oncotype Dx® Prostate**

**Analytic Validity**

In the only study of validity for the Oncotype DX® Prostate test, Knezevic (2013) reported analytical accuracy and reproducibility of Oncotype Dx® Prostate.\[^{83}\] Estimates of analytic precision and reproducibility were derived from analysis of RNA prepared from 10 microdissected prostate tumor samples obtained by needle biopsy. Individual Gleason scores were assigned using the 2005 International Society of Urological Pathology Consensus guidelines.\[^{84}\]

The results showed that the assay could accurately measure expression of the 12 cancer-related and five reference genes over a range of absolute RNA inputs (0.005 to 320 ng); the limit of detection in a sample was 0.5 ng/uL. The analytic accuracy showed average variation of less than 9.7% across all samples at RNA inputs typical of needle biopsy specimens. The amplification efficiency for the 17 genes in the test ranged from 88% to 100%, with a median of 93% (standard deviation [SD] 6%) for all 17 genes in the assay. Analytic precision was assessed by examining variability between replicate results obtained using the same mRNA input. Reproducibility was measured by calculating both within and between mRNA input variation. A low input level of 5 ng mRNA was used to reflect the lowest 2.5 percentile of a tumor sample of 0.023 cm³. When converted to Genomic Prostate Score (GPS) units (unit measure for reporting test results), the standard deviation for analytic precision was 1.86 GPS units (95% CI 1.60 to 2.20) on the 100-unit scale. The standard deviation for reproducibility was 2.11 GPS units (95% CI 1.83 to 2.50) on the 100-point scale. This study provides sufficient evidence to establish the analytic validity of Oncotype Dx® Prostate.

**Clinical Validity**

Brand (2016) combined studies from Klein (2014) and Cullen (2015) using a patient-specific meta-analysis.\[^{85}\] The GPS was compared to the CAPRA score, NCCN risk group, and AUA/EAU risk group. The authors tested whether the GPS added predictive value for the likelihood of favorable pathology above the clinical risk assessment tools. The model including the GPS and CAPRA score provided the best risk discrimination; the AUC improved from 0.68 to 0.73 by adding the GPS to CAPRA score. The AUC improved from 0.64 to 0.70 by adding the GPS to the NCCN risk group. The improvements were reported to be significant but the confidence intervals for AUC were not provided.

Whalen (2016) prospectively evaluated the correlation of GPS with final pathology at RP in a clinical practice setting. Eligible men were 50 years of age and older with more than 10 years of life expectancy, PSA levels of 20 ng/mL or less, stage cT1c-cT2c newly diagnosed, untreated prostate cancer, and who met NCCN classifications as very low risk, low risk, or low-intermediate risk.\[^{86}\] Men were enrolled from May 2013 to August 2014 at an academic medical center. Genomic Health reclassified patients' cancers as “less favorable,” “consistent with,” or “more favorable” than what would have been predicted by their NCCN risk group. The primary
outcome was adverse pathology at RP defined as any pT3 stage and primary Gleason grade of 4 or any pattern 5. Fifty patients had RP pathology and the reclassification results for these participants are discussed here; 21 (42%) met the definition of adverse pathology. The NCCN risk classification categorized two (4%) patients as very low risk, 34 (68%) as low risk, and 14 (28%) as low-intermediate risk. Twenty-three (46%) of patients were reclassified using GPS. Confidence intervals were not provided.

One publication compiled results of three cohorts, two of which were used for test development, of contemporary (1997 to 2011) patients in a prostatectomy study (n=441; Cleveland Clinic database, 1987 to 2004), a biopsy study (n=167; Cleveland Clinic database, 1998 to 2007), and an independent clinical validation study cohort (n=395; mean age, 58 years; University of California, San Francisco Urologic Oncology Data Base, 1998 to 2011).[87]

A study by Salmasi (2018) examined the ability of the test to predict adverse pathology in 134 patients with NCCN very low, low, or intermediate risk prostate cancer, who had additionally undergone MRI testing.[88] MRI results were reported by both UCLA score and Pi-RADSv2. In contrast to the results of other studies, the PSA and MRI scores in this group were not independent predictors of adverse pathology, while the GPS was (OR 3.3, 95% CI 1.74 to 6.62, p<0.001),

Results from the clinical validation study and prostatectomy study provide information on the potential clinical validity of this test. The cohorts had a mix of low to low-intermediate clinical risk characteristics using National Comprehensive Cancer Network (NCCN) or American Urological Association (AUA) criteria.

The clinical validation study was prospectively designed, used masked review of prostatectomy pathology results, and as such met the REMARK (Reporting Recommendations for Tumor Marker Prognostic Studies) guidelines for biomarker validation.[89] The prostatectomy study used a case-cohort design to select a 1:3 ratio of recurrent to nonrecurrent patients. The prespecified primary endpoint of the validation study was the ability of the GPS to predict the likelihood of favorable pathology in the needle biopsy specimen. Favorable pathology was defined as freedom from high-grade or non-organ-confined disease. In the prostatectomy study, the ability of the GPS to further stratify patients within AUA groupings was related to clinical recurrence-free interval in regression-to-the-mean estimated survival curves.

The validation study results showed that the GPS could refine stratification of patients within specific NCCN criteria groupings, as summarized in Table 1. The proportions in Table 1 were estimated from a plot of GPS versus the percent likelihood of favorable pathology.[90]

GPS: Genomic Prostate Score; NCCN: National Comprehensive Cancer Network.
The actual number of patients correctly or incorrectly reclassified between all three categories cannot be ascertained from the data provided. The results suggested that the combination of GPS plus clinical criteria could reclassify patients on an individual basis within established clinical risk categories. However, whether these findings support a conclusion that the GPS could predict the disease-specific survival based solely on the level of pathology in a biopsy specimen is unclear. Moreover, extrapolation of this evidence to a true active surveillance population, for which the majority in the study would be otherwise eligible, is difficult because all patients had elective radical prostatectomy within 6 months of diagnostic biopsy.

The Klein (2014) prostatectomy study, although used to identify genes to include in the GPS, provided estimates of clinical recurrence rates stratified by AUA criteria (Epstein), compared with rates after further stratification according to the GPS from the validation study. The survival curves for clinical recurrence reached a duration of nearly 18 years based on the dates individuals in the cohort were entered into the database (1987-2004). The reclassifications are summarized in Table 2. The GPS groups are grouped by tertiles defined in the overall study. These data suggest the GPS can reclassify a patient’s risk of recurrence based on a specimen obtained at biopsy. However, the findings do not necessarily reflect a clinical scenario of predicting disease progression in untreated patients under active surveillance.

AUA: American Urological Association; GPS: Genomic Prostate Score.

A retrospective cohort study by Cullen (2015) included men with NCCN-defined very low-through intermediate-risk prostate cancer undergoing RP within six-months of diagnosis.[91] The sample was obtained from men enrolled in the Center for Prostate Disease Research longitudinal study at two U.S. military medical centers. A Gleason score of 4 or 5 with non-organ-confined disease was considered adverse pathology. Biopsies were available for 500 (57.9%) of 864 eligible patients; 382 (44.2% of eligible) with both adequate tissue for gene expression analysis and available RP pathology were included in the analysis. Selected patients were older (61.0 years vs. 59.7 years, p=0.013) and had both higher Gleason scores (p<0.001) and NCCN risk classification (29.8% vs 32.9% intermediate, p=0.035). Median follow-up was 5.2 years and biochemical recurrence (BCR) occurred in 62 (15.4%). Adverse pathology was noted in 163 (34%) men. In an analysis adjusted for baseline characteristics, the GPS was associated with BCR-free survival (HR 2.73 for each 20-point increase, 95% CI 1.84 to 3.96) and adverse pathology following RP (HR 3.23 per 20-point increase, 95% CI 2.17 to 4.97). The GPS improved the C statistic for adverse pathology over NCCN risk alone from 0.63 to 0.72 (CIs not reported). Comparisons with other predictors such as CAPRA or Gleason score alone were not reported. Study implications were limited by the low proportion of eligible men in the analysis and differences between excluded and included men.

Clinical Utility
Klein (2014) also reported a decision-curve analysis that they have proposed reflects the
clinical utility of Oncotype Dx® Prostate.[90] The analysis investigated the predictive impact of
the GPS in combination with the Cancer of the Prostate Risk Assessment (CAPRA) validated
tool[92] versus the CAPRA score alone on the net benefit for the outcomes of patients with high-
grade disease (Gleason >4+3), high-stage disease, and combined high-grade and high-stage
disease. They reported that, over a range of threshold probabilities for implementing treatment,
“incorporation of the GPS would be expected to lead to fewer treatments of patients who have
favorable pathology at prostatectomy without increasing the number of patients with adverse
pathology left untreated.” For example, at a threshold risk of 40% (e.g., a man weighing the
harms of prostatectomy versus benefit over active surveillance at 4:6) the test could identify 2
per 100 with high-grade or high-stage disease at a fixed false positive rate compared with
using the CAPRA score alone. However, no confidence intervals were presented for the
decision curve analysis. Thus, an individual patient could use the findings to assess his
balance of benefits and harms (net benefit) when weighing the choice to proceed immediately
to curative radical prostatectomy with its attendant adverse sequelae, or to enter an active
surveillance program. The latter would have an immediate benefit realized by forgoing radical
prostatectomy, but perhaps would be associated with greater downstream risks of disease
progression and subsequent therapies.

Section Summary

No direct evidence of clinical utility was found. Klein’s decision-curve analyses suggest a
potential ability of the combined GPS and CAPRA data to help patients make decisions based
on relative risks associated with immediate treatment or deferred treatment (i.e., active
surveillance). This would reflect the clinical utility of the test. However, it is difficult to ascribe
possible clinical utility of Oncotype Dx® Prostate in active surveillance because all patients
regardless of clinical criteria elected radical prostatectomy within six months of diagnostic
biopsy. Moreover, the validity of using different degrees of tumor pathology as a surrogate for
cancer-specific death is unclear. Reports from validation studies lack precision estimates for
important variables such as risk estimates for recurrence. All validation studies were Simon
category C.

Prolaris®

Analytic Validity

Although there is no reference standard for gene expression profiling tests, other measures of
technical performance are relevant and include reproducibility, tissue-sample adequacy,
potential batch effects, and test-set bias. Warf (2015) evaluated the precision of the Cell Cycle
Progression (CCP) score using six formalin-fixed, paraffin-embedded (FFPE) biopsy (three
replicate scores) and 12 FFPE RP (four to six replicate scores) specimens.[93] Overall precision
was estimated from replicate samples, intended to reflect combined variation from tissue
dissection through gene expression. Across replicate samples, the standard deviation of the
CCP score was 0.1 (95% CI 0.98 to 0.13). After eight weeks of sample storage, results were
similar. In 2013, Myriad Genetics reported 95.3% of samples were adequate to produce a CCP
score.[94]

Clinical Validity: Needle Biopsy, Conservative Management

In 2016, results of a systematic review and meta-analysis supported by the manufacturer were
reported.[86] Published and unpublished studies of prognostic validity or clinical utility of CCP
testing were eligible for inclusion. Seven published studies were identified; five were clinical validity studies. Two are reviewed in the following paragraphs and the remaining validity studies will be reviewed in a subsequent section on post-RP management. The two “utility” studies are discussed in the following section. Two validity studies reported outcomes for disease-specific mortality\cite{96,97} but of the two, only the Cuzick (2012)\cite{96} included newly diagnosed patients, so the pooled outcome is not of relevance in this section.

The more recent study by Cuzick (2015) examined three U.K. cancer registries from 1990 to 2003 to identify men with prostate cancer who were conservatively managed following needle biopsy, with follow-up through December 2012. Men were excluded if they had undergone RP or radiation therapy within six months of diagnosis.\cite{84} A combination of the CCP and Cancer of the Prostate Risk Assessment (CAPRA) scores was used to predict prostate cancer death. There were 989 men who fit eligibility criteria; CCP scores were calculable for 761 (77%) and combined CCP and clinical variables were available for 585 (59%). Median age at diagnosis was 70.8 years and median follow-up was 9.5 years. The prostate cancer mortality rate was 17% (n=100), with 29% (n=168) dying from competing causes. Higher CCP scores were associated with increased 10-year risk of prostate cancer mortality: 7% (CCP score <0), 15% (CCP score 0 to 1), 36% (CCP score 1 to 2), 59% (CCP score >2). A one-unit increase in CCP was associated with a crude HR for death of 2.08 (95% CI, 1.76 to 2.46) and when adjusted for CAPRA score yielded a HR of 1.76 (95% CI, 1.47 to 2.14). For the combined CAPRA/CCP score, the HR for 10-year prostate cancer mortality increased to 2.17 (95% CI: 1.83 to 2.57). The c-statistic for the CAPRA score was 0.74; adding the CCP score increased the C statistic to 0.78 (no confidence intervals for the AUC were reported). Treatment changes after six months were documented in only part of one of the three cohorts; at 24 months, 45% of the men in this cohort had undergone radiotherapy or prostatectomy. Therefore, the potential effect of treatment changes on prognostic estimates is uncertain.

The Cuzick (2012) study examined the prognostic value of Prolaris® for prostate cancer death in a conservatively managed needle biopsy cohort.\cite{96} Cell cycle expression data were read blind to all other data. Patients were identified from six cancer registries in Great Britain and were included if they had clinically localized prostate cancer diagnosed by needle biopsy between 1990 through 1996; were younger than 76 years at diagnosis; had a baseline PSA measurement; and were conservatively managed. Potentially eligible patients who underwent RP, died, showed evidence of metastatic disease within six months of diagnosis, or received hormone therapy before diagnostic biopsy were excluded. The original biopsy specimens were retrieved and centrally reviewed by a panel of expert urologic pathologists to confirm the diagnosis and, where necessary, to reassign Gleason scores.\cite{44} Of 776 patients diagnosed by needle biopsy and for which a sample was available to review histology, needle biopsies were retrieved for 527 (68%), 442 (84%) of which had adequate material to assay. From the 442 samples, 349 (79%) produced a CCP score and had complete baseline and follow-up information, representing 45% of 776 patients initially identified. The median follow-up time was 11.8 years. Ninety deaths from prostate cancer occurred within 2799 person-years.

The primary, unadjusted analysis found a one-unit increase in CCP score associated with a two-fold increase (HR 2.02, 95% CI 1.62 to 2.53) in the risk of dying from prostate cancer. In a multivariate model including CCP, Gleason score, and PSA level, the adjusted HR for a one-unit increase in CCP score was 1.65 (95% CI 1.31 to 2.09). However, changes in HRs may not reflect meaningful changes in absolute risk. It appears that there might be a large change in risk for scores below 2 compared with above 2, but no CIs are reported so it is impossible to draw conclusions. Measures that would suggest improved discriminatory ability (e.g., AUC or
reclassification) compared with an existing nomogram were not reported. The authors did not provide evidence that the test could correctly reclassify men initially at high risk to lower risk to avoid overtreatment, or conversely, correctly reclassify those initially at low risk to high risk to avoid undertreatment.

a. adjusted for Gleason score and prostate-specific cancer level
b. adjusted for Cancer of the Prostate Risk Assessment

In summary, Table 3 displays the association between CCP score adjusted for CAPRA and Table 4 shows the risk of death by groups of CCP score. The CCR score is most relevant as it appears in the sample report provided by the manufacturer. Table 3 demonstrates an association between CCP and risk of death on the relative scale but does not necessarily indicate that there is a difference in absolute risk that would be meaningful for clinical decision making. Table 4 displays the estimated absolute risk of death for the CCP score but notably absent are CIs which would help in interpretation. However, given the data provided, several concerns arise. Even the lowest risk group shown in Cuzick (2012)[96] has a 10-year death rate of 20%, which may be explained by the population characteristics (i.e., not PSA screen-selected, a third with Gleason >7 and half with PSA >25); however, a death rate of 20% is unlikely to be low enough to forgo immediate treatment.

Table 4 does not include the death rates by CCR score; however, the predicted 10-year prostate cancer death rates by CCR score were provided in a figure in Cuzick (2015).[94] The predicted 10-year risk for CAPRA alone compared with CCR was provided in a dot plot. The authors stated that CCR identified 11 men with a CAPRA score of 2 (indicating an estimated 10-year mortality rate of 4%) who “had a higher risk” based on CCR score. From the dot plot, it appears that for these 11 men, the 10-year mortality rate estimated by CCR score ranged from just greater than 4% to about 8%. The authors also indicated that for 31 men with CAPRA of 3 (corresponding to a 10-year risk of death rate of 5.7%) the risk as estimated by CCR was less than 4.0%, from the plot the CCR estimated risk appears to range from about 2.5% to 4% for those 31 men. It is not clear that either of these reclassifications would change estimated mortality enough to alter treatment decisions.

Clinical Validity: Posttreatment (radical prostatectomy and external beam radiation therapy)

Four studies have reported clinical validity in the post-RP management setting. Three of these studies—Cuzick (2011),\textsuperscript{[97]} Cooperberg (2013),\textsuperscript{[87]} and Bishoff (2014)—reported on post-RP patients. Koch et al (2016) reported on post-RP patients with BCR. Freedland et al (2013) reported on post-RT patients but is included in this section for completeness.

Bishoff (2014) examined the prognostic ability of the CCP score in three cohorts: Martini Clinic (n=283, simulated biopsies from FFPE RP specimen), Durham Veterans Affairs Medical Center (n=176, diagnostic biopsies) and Intermountain Healthcare (n=123, diagnostic biopsies).\textsuperscript{[98]} The combined analysis included all 582 patients. Gleason scores were 7 or lower in 93% of men. In the combined cohorts, a unit increase in the CCP score increased the adjusted HR for BCR by 1.47 (95% CI 1.23 to 1.76). Metastatic events (n=12) were too few to draw conclusions. Although the CCP score was associated with increased risk of BCR, the analyses do not allow examining whether the CCP score provides improved discrimination over clinicopathologic variables.

In Myriad-funded study, Freedland (2013) evaluated the CCP score’s ability to predict biochemical recurrence (BCR) in a cohort of men treated with external beam radiation therapy (EBRT).\textsuperscript{[99]} The CCP score was derived retrospectively from diagnostic biopsy specimens of men diagnosed with prostate cancer from 1991 to 2006 (n=141). The primary outcome assessed was time from EBRT to BCR. In a multivariable analysis with Gleason score, PSA, percent positive cores, and androgen deprivation therapy, the HR was 2.11 for a one-unit increase in CCP score (equivalent to a doubling of gene expression) (p=0.034), indicating that CCP provides prognostic information that is not provided by standard clinical parameters. At 10 years post-EBRT, the CCP score was associated with prostate cancer specific mortality (p=0.013). The limitations of this study include small size of the cohort, small number of treatment failures (only 19 patients [13%] had BCR), and short follow-up time. The authors conceded that “definitive conclusions regarding time dependency will require additional studies”.

Cooperberg (2013) sought to evaluate the CCP score in a RP cohort and the incremental improvement over the Cancer of the Prostate Risk Assessment Postsurgical (CAPRA-S) score for predicting BCR employing a prospective-retrospective design (conforming to a PRoBE study design).\textsuperscript{[87]} A prognostic model was developed from the RP cohort described by Cuzick (2011).\textsuperscript{[97]} The validation cohort was obtained from patients identified from the University of California, San Francisco (UCSF) Urologic Oncology Database. Tissue sufficient to obtain a CCP score was available for 413 men (69% of the 600 eligible samples). Both UCSF and Myriad Genetics performed statistical analyses. In the validation cohort, 95% had Gleason scores of 7 or lower, 16% of samples had positive margins, 4% had seminal vesicle invasion, and 23% had extracapsular extension. BCR occurred in 82 men (19.9%). The unadjusted HR for BCR increased by 2.1 (95% CI 1.6 to 2.9) per unit increase in CCP score. A predictive
model for the combined CCP/CAPRA-S developed in the Cuzick (2011)[97] RP cohort applied to the UCSF cohort obtained an AUC for BCR with CAPRA-S alone of 0.73 increasing to 0.77 for the combined CCP/CAPRA-S.

Cuzick (2011) examined the potential use of the Prolaris® CCP test combined with a clinical score following RP, using a retrospective cohort and the prospective-retrospective design for archived samples.[97] The study also included a cohort of men with localized prostate cancer detected from specimens obtained during transurethral resection of the prostate, which is not a population of interest here, and so has not been described. Men conservatively managed post RP between 1985 and 1995 were identified from a tumor registry (n=366 with CCP scores, Scott and White Clinic, in Texas). The primary endpoint was time to biochemical recurrence (BCR) and the secondary end point was prostate cancer death. Myriad Genetics assessed CCP scores blindly. The median age of patients was 68 years and the median follow-up 9.4 years. Gleason scores were 7 or lower in 96%, but margins were positive in 68%. Cancers were clinically staged as T3 in 34%; following RP, 64% was judged pathologic stage T3. CCP score was associated with BCR (adjusted HR 1.77, 95% CI 1.40 to 2.22). Analyses of prostate cancer deaths in the RP cohort were problematic, owing to only 12 (3%) deaths. The clinical score included PSA, stage, positive surgical margins, and Gleason score. The model was optimized using stepwise variable selection (e.g., a development model). The AUC for BCR within five years in the RP cohort was 0.825 for the clinical score and 0.842 for the combined clinical/CCP score. The discriminatory ability of the clinical score is of note. Although the CCP increased the AUC by 2%, whether that improvement might be clinically useful is unclear lacking reclassification or examination of net benefit.

Clinical Utility

One large prospective registry study, funded by Myriad, was recently published that evaluated the impact of the CCP test on treatment decision making for patients newly diagnosed with prostate cancer.[100] Patients (n=1,206) with newly diagnosed prostate adenocarcinoma had the CCP test performed on initial prostate biopsy tissue. Changes in treatment decision making was tracked using the answers provided by physicians in sequential surveys relative to initial therapy recommendations (before cell cycle progression). The CCP test caused a change in actual treatment in 47.8% of patients, 72.1% of which were reductions and 26.9% of which were increases in treatment. For each clinical risk category there was a significant change in treatment modality (intervention vs nonintervention) before vs after CCP testing (p=0.0002). This study did not report any changes in patient-important outcomes, such as biochemical recurrence, cancer-specific survival or long-term survival. Although this study reported a change of management in a modest percentage of patients, there was no evidence that these changes in management lead to clinically important improvements in health outcomes.

Two retrospective survey studies that assessed the potential impact of Prolaris® on physicians’ treatment decisions.[101,102] The authors of each study have suggested their findings support the “clinical utility” of the test, based on whether the results would lead to a change in treatment. Although this information may be useful in assessing the potential test uptake by urologists, it does not demonstrate clinical utility in clinical settings. In a decision-curve analysis, Cooperberg[87] found the CAPRA-S score superior to CCP alone (as well as treat-none or treat-all strategies) in men postprostatectomy. A combined CCP/CAPRA-S predictor appeared only slightly better than CAPRA-S alone for thresholds of approximately 30% or more. For example, at a threshold of 30% (ie, meaning a man would value the harm-to-benefit of treatment such as radiotherapy as 3:7), the combined CCP/CAPRA-S would detect about

---

GT17 | 21
two more men per 100 likely to experience BCR if the false-positive rate was fixed. However, the lack of confidence intervals for the decision-curve analysis, together with the small difference, is consistent with an uncertain net benefit obtained by adding CCP to the CAPRA-S score.

Decipher®

Analytic Validity

Published data on the analytic validity of the Decipher® test consists of one study, which was performed on surgical resection specimens from patients with prostate cancer identified to be in a postsurgery high-risk population. The Decipher® test platform was performed in formalin-fixed, paraffin-embedded (FFPE) tissue to assess the differential expression in the discovery, validation and clinical application. Matched FFPE and unfixed fresh-frozen specimens from paired tumor and normal samples from kidney, lung and colon were compared and the microarray signals derived from the degraded RNA extracted from FFPE specimens was found to be highly analogous to the signals from the RNA in the fresh frozen specimens.

Clinical Validity

The clinical validity of the Decipher® test genomic classifier (GC) has been reported in studies to predict metastasis, mortality or BCR after RP in patients with postoperative high-risk features like pathologic stage T2 with positive margins, pathologic stage T3 disease or a rising PSA. All studies were retrospective and used registry data or clinical records. The development study was a nested case-control design. Owing to apparent overlap in samples, the number of unique patients in the studies is difficult to ascertain. Many studies were supported by GenomeDx, which offers the Decipher® test; all studies identified multiple authors as company employees.

Four studies, including the test (validation) sample from the development study, examined men observed following radical prostatectomy and undergoing adjuvant or salvage radiotherapy. Median follow-up periods ranged from 6.4 to 16.9 years. The distributions of Gleason scores in the studies varied—from 24.3% to 49.3% with 8 or higher and 0.4% to 15.1% with 6 or lower. Extracapsular extension of the tumor ranged from 42.7% and 72.3% of men across of the studies.

A study by Nguyen (2017) included 235 patients who had either RP or first-line radiotherapy (with or without androgen deprivation therapy) between 1987 and 2024, with a median follow-up of six years. After adjusting for treatment and clinical data, the biopsy Decipher® score was associated with five-year metastasis (HR 1.39 per 0.1 unit increase, 95% CI 1.09 to 1.8). The frequency of metastasis within five years was 4.1%, 7.8%, and 21% for the Decipher® low-, intermediate-, and high-risk groups.

Klein (2016) evaluated the ability of the Decipher® GC to predict metastasis from the prostate needle biopsy diagnostic tumor tissue from 56 men. Median follow-up time was eight years. In that time, eight patients metastasized and three died of PCa. Decipher® plus NCCN model had an improved c-index of 0.88 (95% CI 0.77 to 0.96) compared to NCCN alone (c-index 0.75, 95% CI 0.64 to 0.87). Using the Cox multivariable analysis, Decipher® was the only significant predictor of metastasis when adjusting for age, preoperative PSA and biopsy Gleason score (HR 1.72 per 10% increase, 95% CI 1.07 to 2.81, p= 0.02).
Ross (2015) assessed the prognostic accuracy for metastasis through 10 years, excluding men receiving any adjuvant therapy following radical prostatectomy over median follow-up periods of 7.8 and nine years.\cite{115} The investigators reported a 6.5% five-year cumulative incidence of metastases in men with GC scores of 0.45 or lower, compared with 30.3% in those with scores higher than 0.60. The AUCs for development of metastases was 0.76 for the GC. In addition, it was found that combining the GC with the best clinicopathologic tool improve the AUC. The study did not include a “standard” reclassification table, but did report 10-year cumulative incidence of metastases stratified by GC and CAPRA-S. The GC appeared to discriminate within CAPRA-S categories, added little to a score greater than 5.

Den (2015) reported on the use of the Decipher® genomic classifier (GC) to provide prognostic and predictive information into the development of metastases in men receiving post-RP RT (either three-dimensional conformal or IMRT).\cite{104} Genomic classifier scores were calculated from 188 men who were identified within the GenomeDx prostate cancer database with pathologic stage T3 or margin-positive prostate cancer and had received post-RP RT at one of two academic centers between 1990 and 2009. The primary endpoint was metastatic disease (regional or distant) documented on computed tomography or bone scan. Adjuvant versus salvage RT was defined by PSA levels of 0.2 ng/mL or less and more than 0.2 ng/mL before initiation of RT. The clinical characteristics of eligible patients included 72% of men with extraprostatic extension, 35% with seminal vesicle invasion, and 78% with positive surgical margins. Twenty-one percent of patients had a Gleason score of 8 or more. Fifty-one percent of patients received adjuvant RT (89% within 12 months of RP) and overall, patients received RT at a median of five months after RP (range 1 to 160 months). Thirty percent of patients received hormonal therapy with RT. Median follow-up after RP and RT was 10 and 8 years, respectively. Cumulative incidence of metastatic disease at five years after RT for low, average, and high GC scores was 0%, 9%, and 29% (p=0.002). In a multivariate analysis, GC and pre-RP PSA were independent predictors of metastasis (both p<0.01). In the low GC score group (score <0.4) there was no difference in cumulative incidence of metastasis compared with patients who received adjuvant or salvage RT (p=0.79), however, for patients with higher GC scores (≥0.4), the cumulative incidence of metastasis at five years was 6% for patients treated with adjuvant RT compared to 23% treated with salvage RT (p<0.01). The authors concluded that patients with low GC scores are best treated with salvage RT and those with high GC scores with adjuvant RT.

Klein (2014) evaluated whether use of the Decipher® GC test improved accuracy in predicting metastasis within five years following radical prostatectomy (rapid metastasis [RM]).\cite{75} Participants included 169 patients who underwent radical prostatectomy between 1987 and 2008, of which 15 were RM and 154 were non-RM controls. Metastasis developed between 1.7 and 3.3 years (median 2.3 years). Test performance was evaluated both individually and in combination with clinical risk factors. After adjusting for clinical factors, Decipher® was a significant predictor of RM (OR 1.48, p=0.018). Compared to the Stephenson model, the CAPRA-S, and previously reported biomarkers, Decipher® had the highest concordance index (c-index), with the highest c-index achieved with integration of Decipher® into the Stephenson nomogram.

Karnes (2013) prospectively created a randomly selected subcohort from the same initial 1,010 post-prostatectomy patients in the Cooperberg study.\cite{108} Patients with metastasis at diagnosis or with any prior treatment for prostate cancer were excluded. A randomly-selected subcohort was created, with genomic data was available for 219 patients. Following radical prostatectomy, the rates of biochemical recurrence (BCR) at three years was 35% and
metastasis at five years was 6%. Median genomic classifier scores were consistently higher in patients with metastases at last follow-up (mean 6.7 years). Median genomic classifier scores also increased with higher Gleason scores. The authors concluded that the higher net benefit of genomic-based classifiers suggested increased specificity (i.e., lower false positives) compared with clinical-only risk models. Because patients with intermediate risk tumors may progress to advanced disease, the authors recommended further study of genomic classifiers in randomized datasets to determine whether genomic classifier scores from diagnostic biopsy specimens can predict metastasis as well as postoperative specimens. A possible limitation of this study was that nearly 15% of patients were node-positive and 45% received adjuvant therapy. Whether the genomic classifier predicted benefit from local (i.e., radiation) or systemic (e.g., hormone) therapies could not be determined because patients were not randomized to these treatments.

Den (2014) reported that within a Decipher® low-risk group that was treated post-RP with RT, there was no difference in oncologic outcomes (either biochemical failure or metastasis) whether they received adjuvant or salvage RT.[105] For the men classified as high-risk by Decipher, a median four-year PSA-free survival advantage was observed in the patients that received adjuvant versus salvage RT. Of these men classified as high-risk by GC, those who received adjuvant radiation had a 3% cumulative incidence of metastases as compared with 23% incidence of metastasis by eight years in those who delayed treatment and received salvage radiation.

Clinical Utility

Several studies have compared physician’s treatment recommendations before and after receiving GC results.[116-120] Because the studies did not include information on outcomes and clinical validity has not been established, it is not known whether these treatment decisions represent a clinical improvement in management.

Ross (2016) reported results of a retrospective, comparative study of RT after RP for 422 men with pT3 disease or positive margins.[121] The men were from four cohorts previously described (Karnes [2013], Den [2014], Ross [2016], Freedland [2016]). The four treatment groups were adjuvant RT (n=111), minimal residual disease salvage RT (n=70), salvage RT (n=83), and no RT (n=157). The primary endpoint was metastasis. Thirty-seven men developed metastasis and the median follow-up was eight years. Both CAPRA-S (HR 1.39, 95% CI 1.18 to 1.62) and Decipher® (HR 1.28, 95% CI 1.08 to 1.52) were independently associated with metastasis in multivariable analysis. There was no evidence that treatment effect was dependent on genomic risk (interaction p=0.16 for CAPRA-S, p=0.39 for Decipher). Men with low CAPRA-S or low Decipher® scores had a low risk of metastatic events regardless of treatment selection and men with high CAPRA-S or Decipher® scores benefitted from adjuvant RT compared to the other treatments.

PRACTICE GUIDELINE SUMMARY

AMERICAN UROLOGICAL ASSOCIATION (AUA)

In 2013, the AUA published guidelines for the early detection of prostate cancer.[122] Based on a systematic review of the literature, the guideline panel recognized that novel urinary markers, such as PCA3 and TMPRSS2:ERG, may be “used as adjuncts for informing decisions about the need for a prostate biopsy – or repeat biopsy – after PSA screening,” but emphasized the lack of evidence “that these tests will increase the ratio of benefit to harm.”
The American Urological Association and the Society of Abdominal Radiology published a joint consensus statement in 2016 on prostate magnetic resonance imaging (MRI) and MRI-targeted biopsy.[123] The Association recommended:

“In patients with negative or low suspicion magnetic resonance imaging (PI-RADS [Prostate Imaging Reporting and Data System] assessment category of 1 or 2, respectively), other ancillary markers (ie PSA, PSAD, PSAV, PCA3, PHI, 4K) may be of value in identifying patients warranting repeat systematic biopsy, although further data are needed on this topic.”

EVALUATION OF GENOMIC APPLICATIONS IN PRACTICE AND PREVENTION (EGAPP)

In 2013, the EGAPP Working Group published the following recommendations for PCA3 testing in prostate cancer, based on an AHRQ comparative effectiveness systematic review summarized above:[124]

- Evidence was insufficient to recommend PCA3 testing to inform decisions for when to re-biopsy previously biopsy-negative patients for prostate cancer, or to inform decisions to conduct initial biopsies for prostate cancer in at-risk men (e.g., previous elevated PSA or suspicious digital rectal examination).
- Evidence was insufficient to recommend PCA3 testing in men with cancer-positive biopsies to determine if the disease is indolent or aggressive in order to develop an optimal treatment plan.
- The overall certainty of clinical validity to predict the diagnosis of prostate cancer using PCA3 is deemed “low.” Clinical use for diagnosis is discouraged unless further evidence supports improved clinical validity.
- The overall certainty of net health benefit is deemed “low.” Clinical use is discouraged unless further evidence supports improved clinical outcomes.

NATIONAL COMPREHENSIVE CANCER NETWORK

The National Comprehensive Cancer Network (NCCN) guidelines for Prostate Cancer Early Detection (2.2018) suggest considering tests that improve specificity in higher risk patients after negative biopsy, including 4Kscore, percent free PSA, PHI, PCA3, and ConfirmMDx.[125] PCA3 is not recommended for use in the initial biopsy setting. Guideline authors note:

“Biomarkers that improve the specificity of detection are not, as yet, recommended as frontline screening tests. However, there may be some patients who meet PSA standards for consideration of prostate biopsy, but for whom the patient and/or the physician wish to further define the probability of high-grade cancer. A percent free PSA <10%, PHI >35 or 4Kscore (which provides an estimate of the probability of high-grade prostate cancer) are potentially informative in patients who have never undergone biopsy or after a negative biopsy; a PCA3 score >35 is potentially informative after a negative biopsy. The predictive value of the serum biomarkers discussed above has not been correlated with that of MRI. Therefore, it is not known how such tests could be applied in optimal combination.”

The NCCN guidelines for prostate cancer (3.2018)[126] state that:

Men with low or favorable intermediate risk disease may consider the use of the following tumor-based molecular assays: Decipher, Oncotype DX Prostate, Prolaris,
Promark. Retrospective studies have shown that molecular assays performed on prostate biopsy or radical prostatectomy specimens provide prognostic information independent of NCCN risk groups. These include, but are not limited to, likelihood of death with conservative management, likelihood of biochemical progression after radical prostatectomy or external beam therapy, and likelihood of developing metastasis after radical prostatectomy or salvage radiotherapy.

The discussion section notes that the clinical utility has not been established in prospective RCTs or comparative effectiveness studies.

U.S. PREVENTIVE SERVICES TASK FORCE RECOMMENDATIONS

The U.S. Preventive Services Task Force published recommendations for Prostate Cancer Screening on May 2012. Genetic tests addressed in this policy, including PCA3, were not mentioned.

SUMMARY

There is not enough research to recommend using gene-based tests for prostate cancer screening, detection and management, as many important characteristics of these tests have not yet been determined. Some research shows that they might help predict the diagnosis or prognosis of prostate cancer, but it is not yet known how much information they add to currently available tests. More research is needed to demonstrate how these tests can improve outcomes for patients. Therefore, use of gene-based testing for screening, detection, and management of prostate cancer is considered investigational.
